ENOME GENERATION

Sequence Comparison with OXTR

Sequence Comparison with OXTR

Did you know that humans are, on average, 99.9% genetically identical? Only 0.1% of all our DNA bases are different, but those differences are what influence our traits and help make us each who we are.

The oxytocin receptor (*OXTR*) gene codes for the oxytocin receptor (OXTR) protein, which functions as a receptor for the hormone and neurotransmitter oxytocin. Variants in the human *OXTR* gene are associated with differences in social ability, emotional sensitivity, and response to emotional stress. In this activity, you'll compare *OXTR* DNA sequences from different individuals and different organisms.

When comparing DNA sequences, **percent identity** provides a measure of how similar two sequences are. The formula for percent identity uses the total number of nucleotide **positions** in the sequence comparison and the number of nucleotide positions that are different, or **divergent**, between the sequences:

$$Percent \ Identity = \frac{\# \ positions - \# \ divergent \ positions}{\# \ positions} \ x \ 100\%$$

Part 1. Compare to a Reference Sequence

One common type of sequence comparison is comparing an individual's DNA sequence to a reference sequence. A **reference sequence** is a DNA sequence that is assumed by scientists to be a representative example of the genetic material of a specific species. Reference sequences are typically created by combining the DNA sequences of multiple individuals from the same species.

Comparing an individual's DNA to a reference sequence allows us to identify variants, or differences, between the individual's DNA sequence and the reference.

In this example, we will compare an individual person's DNA sequencing data for the *OXTR* gene to the human reference sequence for *OXTR* to identify which *OXTR* gene variant that person carries. We'll call this person **Jean**.

The sequence comparison below looks at a portion of the OXTR gene for two sequences:

- The **Query** sequence is **Jean**'s *OXTR* sequence data.
- The **Subject** ("Sbjct") sequence is the human **reference** sequence for *OXTR*.

When comparing sequences, it can be helpful to record the source of each sequence. In the figure below, write in which sequence is from **Jean** and which is the **reference** sequence.

Chict		G	
Query	1	GGATCCTCAGTCCCACAGAAACAGGGAGGGGCTGGGAAGCTCATTCTACAGATGGGGAAA	60

1.	How many nucleotides are different between the two sequences within this portion of the <i>OXTR</i> gene? What is/are the variant nucleotide(s) in the individual's DNA sequence and the reference DNA sequence?
2.	In this comparison, there are 60 positions total. What is the percent identity for this comparison?
3.	The entire human <i>OXTR</i> gene sequence is 19,206 nucleotides. What is the percent identity for the entire <i>OXTR</i> sequence? You can assume that all the other nucleotides are the same between the two sequences. Round your answer to two decimal places.
sequen Since h	mes researchers know which gene a DNA sequence is from, but other times they don't. Comparing ices and calculating percent identity can help them figure out which gene their sequence is from. In the sequence is grown as are 99.9% genetically identical to each other on average, a very high percent identity its more confidence that the sequence is from a given gene.
4.	If you didn't know which gene Jean 's DNA sequence was from, would you feel confident that this sequence was from <i>OXTR</i> given the percent identity you calculated in question 3? Why or why not?
5.	What if the percent identity was 99%? 95%? 75%? Justify your answer.

Part 2. Compare Across Species

Imagine that you are a researcher investigating whether genetics can impact social behavior, and you want to learn more about the *OXTR* gene. You plan to use a model organism to conduct some experiments to better understand the impact of the *OXTR* gene on social behaviors. Model organisms, such as mice and fruit flies, are often used as a representation of human biology and behavior because they are easier to study in controlled environments and share much of the same physiology as humans.

You discover that mice also have an OXTR gene. How similar is the mouse OXTR gene to human OXTR?

Start by looking at a small section of the coding region of the *OXTR* gene, comparing the mouse reference sequence (**Query**) to the human reference sequence (**Sbjct**). When comparing across species, it can be helpful to record which sequence corresponds to which organism. In the figure below, write in which sequence is **mouse** and which is **human**.

4.	What is th	ne perc	ent identity of this section of the OXTR gene?	

The percent identity for the comparison of the whole protein coding sequences of human *OXTR* and mouse *OXTR* is 92%. The percent identity of mouse and human genes is 85% on average, but it varies from 60% to 99% for individual genes.

60% to	99% for individual genes.
5.	Given an 92% identity for <i>OXTR</i> and knowing that mice are often used as a model organism to study human biology, would you feel confident using mice as a model to study <i>OXTR</i> ? Justify your answer.
6.	What other information might you want to know about the mouse <i>OXTR</i> gene or protein to help you make your decision?
time. Ir	ring DNA sequences across species can also provide information about how species evolved over in general, the greater the percent identity of DNA sequences between two species, the more y they have shared a common ancestor. It takes time for genetic differences to accumulate, so ms with fewer genetic differences are typically more closely related.
7.	Which species would you expect to have a more similar <i>OXTR</i> DNA sequence to humans: mice or chimpanzees? Justify your answer.

Part 3. Compare Within Species

Another type of sequence comparison is comparing the DNA sequences of different genes within the same species. Comparing different genes within the same species can help scientists identify gene families.

Gene families are groups of genes with similar functions. Comparing sequences helps identify gene families because a gene's sequence determines its associated protein's structure, which determines protein function. This is especially useful in organisms where a full genome sequence is not known. By comparing new gene sequences to known genes, scientists can to determine if the new gene serves a similar function to a known gene.

Comparing genes within species can also provide us information about evolution. Sometimes, as species evolve, genes get duplicated. Over time, these gene duplicates accumulate changes and become different enough that they serve different, yet related, functions.

Let's look at an example. *OXTR* is in the same gene family as arginine vasopressin receptor 1A (*AVPR1A*). How similar are these two sequences?

Start by comparing a small section of the human AVPR1A reference sequence (Query) to the human OXTR reference sequence (Sbjct). When comparing sequences, it can be helpful to record the source of each sequence. In the figure below, write in which sequence is from AVPR1A and which is from OXTR.

- 1. How many nucleotides are different between the two sequences? What types of differences are they?
- 2. What is the percent identity for this comparison?

Overall, human AVPR1A has a 57% identity with human OXTR.

3. Given this percent identity and what you know about the function of OXTR, what might you predict the function of AVPR1A in the body to be?
